19. ABSTRACT (Continue on reverse if necessary and identify by block number) <b>Existing criteria for exposure to impulse noise do not provide any explicit means for evaluating exposures for which the peak SPL of the impulses varies in any given exposure day. Approaches to evaluating such exposures have included the application of a "proportional dose" method such as used with continuous noise or the use of an average level. Implicit in these approaches is the assumption that the order in which a sequence of variable intensity impulses is presented is not important. This same assumption is also implicit in any energy-based exposure criteria. This report presents the results of a pilot experiment designed to test the validity of this assumption. Two groups of chinchillas were exposed to a sequence of 100 impulses. One group received 90 exposures at 138-dB peak SPL impulses followed by 10 exposures at 146-dB peak SPL impulses; the second group received the same series of impulses but in reverse order. The results from these two groups were compared to the results of 100 exposures at 147-dB peak SPL impulses from a report by Patterson et al., (1986). CONTINUED ON BACK</b>

19. ABSTRACT CONTINUED

- The 139-dB peak SPL exposure had the same total energy as the two variable intensity exposures. The results of the three equivalent energy exposures showed that exposures having equal energies could produce statistically different levels of hearing trauma. However, while the mean data were very suggestive in showing an effect of the presentation order, this result did not hold up to statistical analysis because of a large intersubject variability.

## Introduction

The Committee on Hearing, Bioacoustics and Biomechanics (CHABA) of the National Academy of Sciences (1968), issued its "Proposed damage risk criterion for impulse noise (gunfire)." This criterion defines an acceptable exposure for 100 impulses per day and provides a trading rule which allows the derivation of exposure limits for exposures other than 100 impulses per day. There is an implicit assumption in this approach that the intensity of all the impulses is the same. There is no explicit procedure for estimating the hazard when a daily exposure consists of impulses whose peak sound pressure level (SPL) varies during the course of the day. The CHABA document has served as the basis for our current military exposure limits, MIL-STD-1474(C) (1979). This military document has no explicit way of treating exposures to different intensities within the same day. Analogous with the procedures used to evaluate steady state noise exposures, the U.S. Army has adopted a "proportional dose" procedure. For each intensity, an allowable number of rounds is calculated. An exposure is considered acceptable, if the sum of the fractions resulting from dividing the actual number of rounds by the allowable number of rounds is less than one.

Unpublished data collected during the developmental testing of some weapons shows a bimodal distribution of intensities in which about 10 percent of the rounds are 8 to 10 dB higher than the others. There have been suggestions made that the hazard of these weapons should be estimated by computing an average level. There is no data available from exposures to variable intensities to support such an approach. Other approaches to the evaluation of variable intensity exposures can be based upon equal energy considerations. However, if one accepts that an equal energy based measure of an impulse noise exposure can be related directly to the hazards associated with that exposure, then the order in which a series of higher and lower peak SPL impulses is presented should not be important in the final trauma to the auditory system.

The study reported here was undertaken to provide an initial set of data relevant to some of the above issues. Specifically, two groups of chinchillas were exposed to 100 impulses. One group was subjected to 90 exposures, 139-dB peak SPL impulses followed by 10 more at 146-dB SPL. The second group was given the same exposure but in the reverse order. The effect of these two equal energy exposure conditions on the auditory system was evaluated in terms of threshold shift (TS), permanent threshold shift (PTS) and sensory cell loss.

### Methods and procedures

The methods and experimental paradigm were identical to those presented in Patterson et al., (1986) and thus will not be repeated in detail here. Basically, an avoidance conditioning paradigm was used to obtain pre- and postexposure threshold measurements at 10 audiometric test frequencies between 0.125 and 8 kHz. Thresholds were followed after exposure at regular intervals over a period of 30 days, at which time the animals were euthanatized for surface preparation histology. Each animal was individually exposed at a normal angle of incidence to one of the two exposure conditions identified as H/L or L/H in Table 1. The exposures consisted of the presentation of 100 impulses at the rate of one per 3 seconds. Each experimental group consisted of six animals. The impulses were presented to two different groups of animals in two different orders. The first group was exposed to 90 impulses with a 138-dB peak SPL followed by 10 impulses with a 146-dB peak SPL, the L/H group. The second group received the 10 at 146-dB peak SPL impulses first, followed by the 90 at 138-dB peak SPL, the H/L group. Comparison between these two exposures conditions will be made in terms of the amount of threshold shift, permanent threshold shift, and sensory cell loss produced. Upper and lower bounds for the expected TS, PTS, and cell loss were established using the results from Patterson et al., (1986) where animals were exposed to 100 similar impulses but at 147-dB peak SPL (Reference group I) or 139-dB peak SPL (Reference group II). A comparison of the various energies of the exposure conditions from the Patterson et al., (1986) reference conditions, as well as, the H/L and L/H exposure conditions is presented in Table 1. All the impulses were similar in the pressure-time (p-t) plane. The impulses were computer generated (Patterson et al., 1986). The p-t history and energy spectra of the type of impulse used is shown in Figure 1. From the pressure-time history of the impulsive stimulus, the integral of pressure squared over time shown in Table 1 was computed to obtain the total sound exposure level (SEL) re: 20 Pa sec for each exposure condition (Young, 1970).

### Results and discussion

The mean preexposure audiogram for the 12 animals used in these experiments along with the normative data of Miller (1970) is shown in Figure 2. The group mean thresholds for the two groups are shown in Table 2. A two-way analysis of variance showed that there was no statistically significant difference in the preexposure thresholds between the two groups ( $F = 0.32$ ,  $df = 1/10$ ), nor was there a statistically significant interaction between the main effects of group and

frequency ( $F = 1.50$ ,  $df = 9/90$ ,  $p < .05$ ) which was expected given our knowledge of the chinchilla audiogram (Fay, 1988). For each animal, threshold shifts were computed by subtracting that animal's preexposure threshold from the postexposure threshold at each audiometric test frequency. The audiometric and histological effects of each exposure were documented as follows:

(1) The mean threshold shift recovery functions over a 30-day period for each group and each test frequency (Figures 3 through 12).

(2) The maximum TS (TSmax) for each group and for each test frequency (Figure 13).

(3) The permanent threshold shift (PTS) for each group and for each test frequency (Figure 14).

(4) The group mean outer and inner hair cell loss (OHC and IHC) within octave band lengths of the basilar membrane at the indicated frequencies (Figure 15).

In Figures 3 through 15, bars represent the standard error of the mean. If no bar is present, the standard error was less than the size of the symbol. All the individual animal data and group mean data summaries can be found in the Appendix.

From the mean recovery curves shown in Figures 3 through 12, the general impression is that the low peak followed by the high peak sequence of impulses (L/H) produced the greater threshold shift over the entire 30-day recovery period. For the most part, the two sets of recovery functions for groups L/H and H/L are approximately parallel to each other over the 30-day course of recovery. A statistical analysis of the recovery functions was not performed to establish whether or not the apparent differences in the recovery functions are in fact statistically significant. Instead, attention will be focused on the TSmax variable which is a good index of the acute effect of an exposure (Hamernik et al., 1988), and on the permanent effects quantified by PTS and sensory cell loss.

The experiment was designed to probe at two issues; (1) to what extent do equal energy exposure conditions produce equivalent changes in the independent variables? and (2) to what extent does the order of impulse presentation (which does not affect the total energy of an exposure) affect the dependent variables? A graphical comparison among the experimental groups for the mean TSmax, PTS and sensory cell loss variables is shown in Figures 13, 14, and 15 respectively. The number of impulses and the peak levels in the L/H and H/L groups were chosen so that the mean peak level and the total

SEL would be approximately the same as the Reference II group. Thus, the Reference II group would serve as another equivalent energy exposure condition and as a lower bound to what would be expected from the L/H and H/L group. The Reference I exposure condition with 7 dB greater total energy serves as an upper bound for the expected trauma.

The data in Figures 13 to 15 was first subjected to a two-way analyses of variance with repeated measures on one factor (frequency). Each analysis included the L/H, H/L, and Ref. II groups (The 2.8 kHz test frequency was not collected in the Patterson et al., (1986) study and therefore was excluded from this analysis). The summary table for this analysis is presented in Table 3. The main effect of exposure was not statistically significant for any of the four analyses. However, the interaction of exposure and frequency was significant for both audiometric measures (TSmax):  $F = 1.87$ ,  $df = 16/120$ ,  $p < .05$ ; PTS:  $F = 2.04$ ,  $df = 16/120$ ,  $p < .05$ ), indicating there was a significant effect of the noise exposure on maximum threshold shift and PTS and that this effect was dependent upon the test frequency at which the dependent variable was measured. The same was not true for the histological variables where neither the main effect of exposure nor the interaction of exposure and frequency was statistically significant. The main effect of frequency was statistically significant for all four analyses indicating the effect of the exposure differed across the audiometric test frequency and place on the basilar membrane. Thus, although the three exposure groups had the same total energy there were frequency specific differences among the dependent variables used to quantify the results of the exposure.

A posthoc analysis of differences in audiometric variables between the L/H and H/L groups in Figures 13 to 15 was performed using the Student-t distribution. There were statistically significant differences between the two groups for both audiometric variables at the 0.125 kHz test frequency (TSmax):  $t = -2.47$ ,  $df = 10$ ,  $p < .05$ ; PTS:  $t = -2.84$ ,  $df = 10$ ,  $p < .05$ ). There was also a significant difference in TSmax measured at the 2.8 kHz test frequency ( $t = -2.60$ ,  $df = 10$ ,  $p < .05$ ) and in PTS at the 1.4 kHz test frequency ( $t = -2.24$ ,  $df = 10$ ,  $p < .05$ ). All other analyses among these groups were not statistically significant, although many approached significance at the 0.05 level.

In order to determine if the sequence in which a series of variable intensity impulses is presented is important, two-factor analyses of variance with repeated measures on one factor (frequency) were performed on TSmax, PTS, and inner and outer hair cell losses using only the groups L/H and H/L. The results are summarized in Table 4. The main effect of the

order of impulse presentation was not statistically significant for any of the four dependent measures employed. Likewise, there were no statistically significant interactions between order and frequency although this interaction approached statistical significance for the PTS measure ( $F = 1.95$ ,  $df = 9/90$ ,  $p < .055$ ). The main effect of frequency was statistically significant for all analyses.

### Conclusions

Based upon a visual inspection of the mean data shown in Figures 14 and 15, there would appear to be clear differences between the L/H and H/L groups for the PTS measures and clear differences between the three equal energy groups for the PTS and cell loss measures. However, the standard deviations in these data are large, for example, on the order of 15 to 20 dB for the PTS data (See Appendix). Thus, while the mean data and the statistical analysis are suggestive of some potentially interesting effects, it is going to be necessary to increase the experimental sample size before clear statements can be made about the effects of the presentation order of impulses or how to evaluate exposures with variable peak intensities. The one clear conclusion from these data is that the Reference I and II exposure conditions do clearly represent upper and lower bounds to the pathology produced in the L/H and H/L groups.

Appendix

Individual data and group  
summary statistics

### Guide to the appendix

The individual and summary statistics for each experimental group are presented in the appendix that follows. The following paragraphs present a brief description of the contents of the data appendix. In this summary, only a single exposure group is described. All the remaining exposure groups are organized in the same manner.

#### Group title page

The group title page indicates the exposure that each animal in this group received [e.g., 138 dB peak SPL (90x), 146 dB peak SPL (10X)] and the subjects that comprise this group.

#### Preexposure and permanent threshold shift audiograms

The top panel depicts the mean preexposure thresholds for this group. The error bars on this figure and all others in the appendix represent one standard deviation plotted above and below the mean. The lower panel presents the group mean PTS.

#### Preexposure, postexposure and PTS measurements

This page tabulates the pre- and postexposure thresholds (in dB SPL) for each subject as well as the group mean and standard deviation. PTS is computed by subtracting the preexposure threshold from the postexposure threshold for each subject.

#### Recovery threshold shifts

The threshold shifts measured at frequency intervals following noise exposure are in this table.

#### Total cell loss summary

The total sensory cell losses for this group are presented in the top portion of this table. The lower position of the table presents the mean and standard deviation for the total number of inner and outer hair cells missing along octave band lengths of the cochlea.

#### Total cell losses

The total sensory cell losses in octave band lengths of the cochlea for each animal that comprises the exposure group are presented in this table. Also included at the end of the table are the group mean and standard deviation for each octave band length.

### Percent sensory cell losses

This table presents the percent sensory cell losses in octave band lengths of the cochlea for each animal in this group. Also included are the means and standard deviation for each sensory cell and octave band length.

### Cochleograms and PTS audiograms

These figures present cochleograms and PTS audiograms for each animal in the exposure group. The cochleograms show the percent inner and outer hair cell losses for each 0.24 mm segment of the basilar membrane. The PTS audiogram is plotted to allow easy comparison of the PTS and cell loss resulting from the noise exposure.
